Study of surface heat inversions characteristics around Baghdad station

Key words: heat inversion, frequency, relative frequencies, inversion height

Introduction

Increase of temperature with height in the troposphere is called temperature inversion (Kahl, Serreze & Schnell, 1992; Li et al., 2015). Inversion is the reflection at the air temperatures of the natural air layers. Ideally warm air rises while the cold air comes down, causing the air around us to mix and move. This process is called convection, in which the temperature decreases with elevation. Air temperature inversion is one of the most important meteorological phenomena, in which atmospheric lapse rate is inverted i.e. air temperature increases with height instead of decreasing (Yasmeen, 2011).

During the night the ground loses heat and the low-level air cools this results in air temperature increasing with height and the temperature profile is said

to be inverted. When this occurs close to the ground it is called a surface heat inversion (Al-Jiboori, 2015). Conditions that favour the development of a strong surface inversion are calm winds, clear skies, and long nights. Calm winds prevent warmer air above the surface from mixing down to the ground, and clear skies increase the rate of cooling at the earth's surface. Long nights allow for the cooling of the ground to continue over a longer period of time, resulting in a greater temperature decrease at the surface (Davidson & Spink, 2018). Many of the climatological inversions are restricted to the surface heat inversions or the first elevated inversions (Tyson, Preston-Whyte & Diab, 1976). The first stable layer, an inversion layer, encountered in a temperature profile is in many cases, and is important as it plays a central role in controlling air pollution dispersion (Milionis & Davies, 1992).

Pollutants spread in the stable atmosphere throughout the heat inversion

downward since the pollutants reflect from the top of the thermal inversion towards the earth's surface, where the top of the inversion limits the movement of the pollutants to stop the spread towards up (Zhang & Li, 2011). Concentration of key air pollutants depends strongly upon the stability conditions in the lower atmosphere. Heat inversions, inversion layer height, and atmospheric stability, are probably the most important meteorological conditions controlling atmospheric pollution dispersion (Heidorn, 1978). Air temperature inversions are a common feature of pollution episodes around the world (Malek, Davis, Martin & Silva, 2006). Several studies on the effect of atmospheric conditions on air pollution related air pollution episodes with heat inversions (Janhäll, Olofson, Andersson, Pettersson & Halloquist, 2006).

Many studies have emphasized on the surface heat inversion for example Guédjé, Houéto and Hougninnou (2017) using daily (midnight and mid-day) upper-air meteorological data, found highest frequencies of elevated inversions was found in summer months whereas the peak of surface-based was in winter (Guédjé, Houéto & Hougninnou, 2017). The aim of this work focuses on studying the frequency of heat inversions near to the earth's surface and variation of the heat inversions height in Baghdad for the period 2013–2014.

Site and data

Weather station is located at the International Baghdad Airport with geographical coordinates: latitude 33.14° N

and longitude 43.34° E. The elevation of the station is at 33 m above mean sea level. This station is located in a suburb about 16 km west of downtown Baghdad in the Baghdad governorate (Al-Jiboori & Jaber, 2018).

For the purpose of studying this research were obtained radiosonde data, which include the temperature and elevation of the Baghdad station belonged to Iraqi Meteorological Organization and Seismology (IMOS) for a period of one year (2013–2014). The station is supposed to give the observations two times a day (00:00 and 12:00 GMT), but unfortunately it is available only one time (00 GMT). Data have been provided to us in the form of variable levels and has been processed and tabulated on a daily basis for the purpose of this work on this model. The data contains air temperature, pressure, height, dew temperature, humidity and wind speed with its direction. They saved in a CD.

Methodology

Using MATLAB software the air temperature profile was plotted for all the data used for the study the surface inversion profiles were selected to execute this work one of the air temperature distribution profiles with the height of each day in which a surface heat inversion occurred to illustrate and understand what happens during the heat inversion as in Figure 1.

Surface heat inversion cases were tested for the purpose of calculating frequencies of inversions close to the earth's surface in two ways:

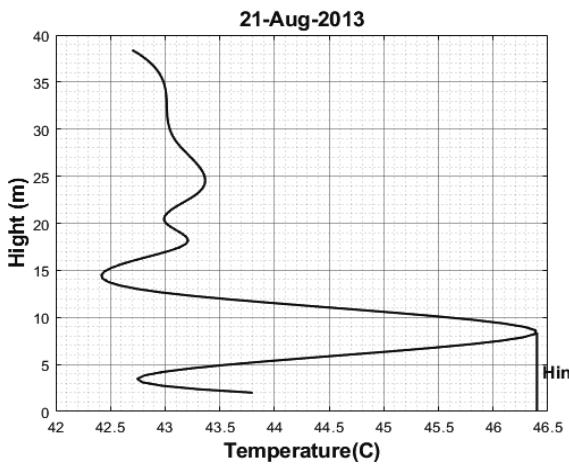

FIGURE 1. Air temperature profile of Baghdad for 21 August 2013

- a) A relative frequencies (RF) of the monthly and seasonal surface heat inversions where the relative frequency of the inversions for a given month represents the number of inversion cases for that month divided by the number of days of the month multiplied by one. The relative frequency of the inversions of a particular season represent the number of inversion for that season divided by the total number of days during each season multiplied by 100 as given:

$$RF = N_{in} / N_T \cdot 100 \quad (1)$$

where:

N_{in} – number of surface heat inversion cases;

N_T – total number of month or season.

- b) Frequency average of monthly and quarterly heat inversions where the frequency of inversion for a given month represents the number of inversion cases for that month divided by the number of days of the month. The frequency average (FA) of in-

versions for a particular season represents the number of inversion for that season divided by the number of days of separation as shown in equation (1) but without multiplying by 100:

$$FA = N_{in} / N_T \quad (2)$$

The height of the inversion layer represents the high end of the inversion layer from its base at which the highest air temperature is and then, it was calculated on a quarterly basis starting from the winter.

Results and discussion

Frequencies of surface heat inversions

The focus was on studying of the frequencies of heat inversions near the earth's surface. Relative frequencies of the monthly inversions near the earth's surface were calculated. The results of RF are highest in September with percentage of 70%, while the lowest is in the March and October with percentage of 19%. As shown in Table 1, which

TABLE 1. Number of monthly surface heat inversions cases

Month	Number of inversion	RF (%)
January	11	35
February	17	61
March	6	19
April	14	47
May	13	42
June	14	47
July	18	58
August	14	45
September	21	70
October	6	19
November	9	30
December	16	52
Sum	159	44

shows the percentages of frequencies of low-level inversions per month during the year studied.

However, the relative frequencies of relative surface inversions were calculated and the results were the winter and

TABLE 2. Number of seasonal surface heat inversions cases

Season	Number of inversion	RF (%)
Winter	44	49
Spring	34	37
Summer	45	49
Autumn	36	40

summer recorders the highest frequency of inversions (49%), while the lowest frequency was in the spring (37%), frequencies of surface inversions occurring during the seasons of the year are reported in Table 2, which shows the percentage of frequency of surface heat inversion per season, more frequencies are at winter and summer.

The monthly and seasonal frequencies average of inversions was calculated and using equation (1) and Figure 2, which shows the monthly frequency of the years taken for study starting from the January and the results were that the frequency was the highest value for it in

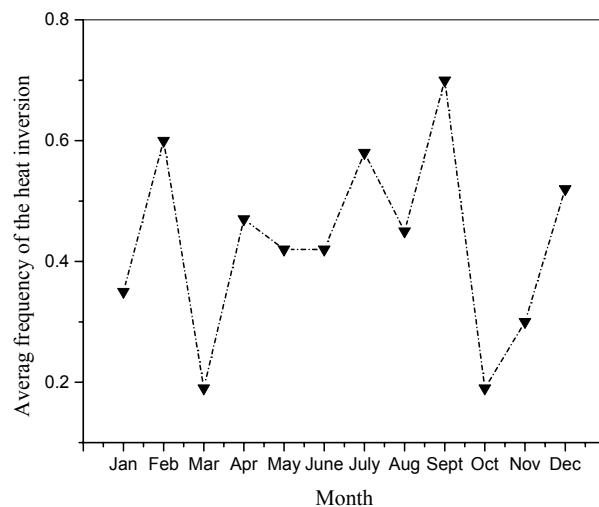

FIGURE 2. Frequency of monthly surface heat inversions

September with value 0.7 and the lowest value of 0.19 is in March.

As for the rate of recurrences of the surface inversion of a particular season and the results are plotted as in Figure 3 which shows a change in the frequencies average of inversions per season and was the highest value for *AF* in the summer and winter where the values were almost equal the summer and winter comes at the first rate and the average is 0.49, followed the autumn it was the average is 0.4 and the lowest frequencies average of surface inversions in the spring, which is 0.37.

of inversions near the surface, which is the quiet winds where the warm air prevents the surface from mixing at the low of the earth, a clear sky that increases the cooling rate on the earth's surface and the long nights that continue to cool the earth over a longer period of time, resulting in a lower temperature on the surface and the inversion occur. Spring season is characterized by low average frequency because it is a transitional seasons characterized by sudden change in the atmosphere that causes the reduction of recurrence of the inversion. The

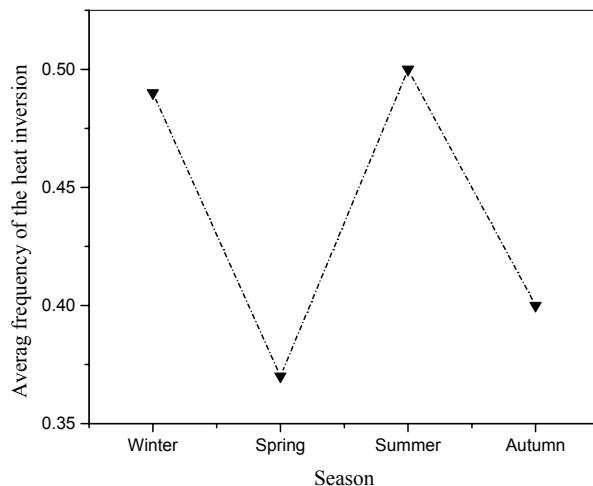

FIGURE 3. Frequency of seasonal surface heat inversions

The high frequencies average in the summer can be explained to the fact that it is during the summer, a very hot day follows a cold-night night where the sky free of clouds and low relative humidity to the increase in the rates of ground radiation and cooling of air near the surface of the earth, which helps to form inversion and can be applied to the autumn.

In the winter, there are geological conditions that increase the incidence

increase in average frequency inversions in the autumn compared with the spring is due to the large decrease in the amount of clouds and wind speed.

Surface inversion height

Surface heat inversion cases were one of the surface heat inversion characteristics is its height which calculates as the height of the inversion layer on the surface up to a height where the air tem-

perature decreases with height. The inversion layer height represents the high end of the inversion layer of its base. In general, height of the surface heat inversion (H_{in}) may follow the general expression give as:

$$H_{in} = a + b \cdot t + c \cdot t^2 \text{ [m]} \quad (3)$$

where:

a, b, c – empirical constants derived from data of height and dates;

t – number of date.

Equation (3) becomes linear if $c = 0$. The values of these constants are derived for each season and reported in Table 3. Figures 4 shows the variations in the height of the layer of surface heat inversion during the winter that the highest

TABLE 3. The values of empirical constants for seasons

Season	a	b	c
Winter	40.4	0	–
Spring	35.1	0.04	–
Summer	-114.6	1.9	-0.006
Autumn	–	–	–

rise in the winter is 50.5 m. The results of inversion heights in winter shows approximately a constant behaviour during this season with a value of about 41 m.

Figures 5 represents the change in the height of the surface heat inversion during spring, the highest rise of the base of the inversion in the spring was 51.9 m. The results of inversion heights in spring shows linear behaviour during this season with a value of about 37 m. In summer, the results of inversion heights have different behaviour from other seasons where non-linear behaviour is obvious. Figures 6 shows the change in the height of the surface heat inversion during the summer and the highest rise in the summer is 55.8 m. Figures 7 shows the distribution of the height of the surface inversion during autumn. The highest altitude in the autumn was 52.6 m, fitting during this season because it shows owing to the high scatter of H_{in} values, the line fitting could not draw. The reason may be caused by receiving a different amounts solar radiation energy during this season.

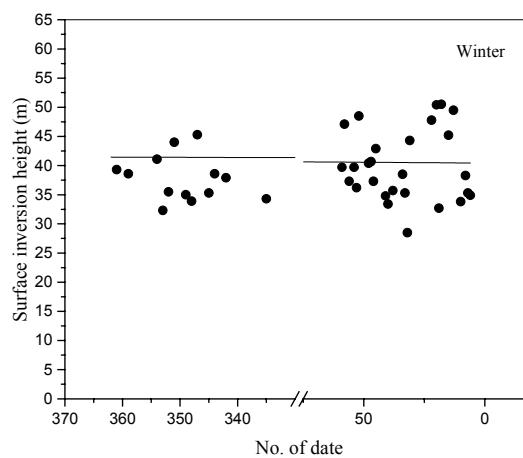

FIGURE 4. Daily variation in the height of the inversion during in the winter

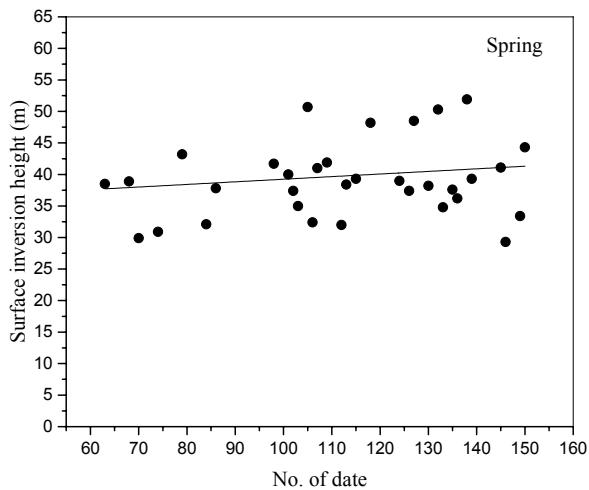

FIGURE 5. Daily variation in the height of the inversion during in the spring

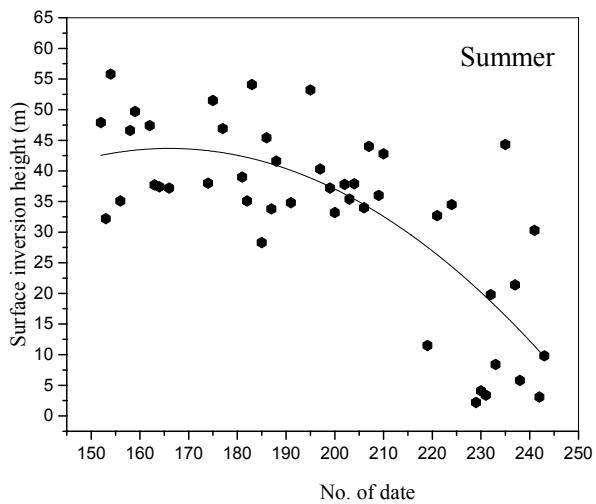

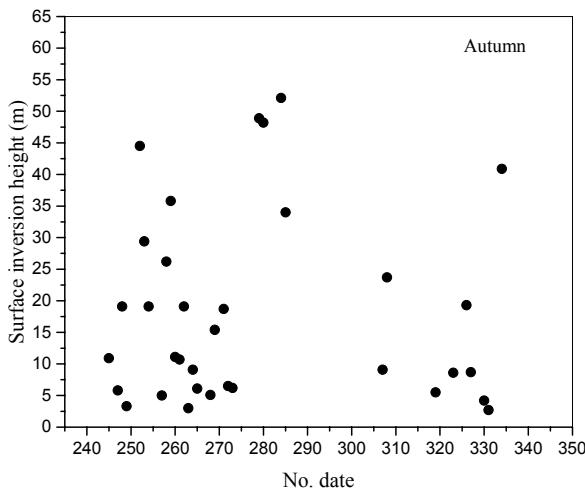

FIGURE 6. Daily variation in the height of the inversion during in the summer

After a comparison among the seasons, the results showed that the highest value for the rise of the surface layer of the surface heat transfer was in the summer where it was 55.8 m as shown in Figure 7 and that the lowest value was in the winter season which is 50.5 m as shown in Figure 5. The reason for this is due to the air temperature differences

between the seasons where the rise in air temperature during the summer to raise the air to higher levels than in winter and spring. The seasonal variation was chosen because the period covered by the study is not long and one year only, so do not take the differences between the years in mind despite the possibility of giving us insights about the study.

- characteristics for Baghdad city. This inversion plays an important role in the study of concentrations of pollutants as well as its effect on spraying insecticides, which starts from a height of 2 m using the daily radiosonde data (midnight) of the period of 2013–2014 obtained from the Iraqi Meteorological Organization and Seismology. The frequencies average of the heat inversion was studied on a monthly and quarterly basis. It was clear from the study that surface heat inversion shows the highest monthly frequency average in the September; the lowest monthly frequency average in the March; highest seasonal frequency average in the summer and the lowest seasonal frequency average in the spring. As for the relative frequencies of the monthly and seasonal of the surface heat inversion was calculated, it was found that 49% occurs during the summer months also winter record the same relative frequencies of the surface heat inversion in the summer. It was done through this research calculated height of the surface heat inversion the results were heights inversion in winter.
